SUMMARY

High-grade serous ovarian carcinoma presents significant clinical and therapeutic challenges. Although the traditional model of carcinogenesis has focused on the ovary as a tumor initiation site, recent studies suggest that there may be additional sites of origin outside the ovary, namely the secretory cells of the fallopian tube. Our study demonstrates that high-grade serous tumors can originate in fallopian tubal secretory epithelial cells and also establishes serous tubal intraepithelial carcinoma as the precursor lesion to high-grade serous ovarian and peritoneal carcinomas in animal models targeting the *Brca*, *Tp53*, and *Pten* genes. These findings offer an avenue to address clinically important questions that are critical for cancer prevention and early detection in women carrying *BRCA1* and *BRCA2* mutations.

INTRODUCTION

Epithelial ovarian cancer is the most lethal gynecologic malignancy in the United States with an annual mortality rate of 15,000 (Siegel et al., 2012). High-grade serous ovarian carcinoma (HGSC), the most common and aggressive subtype, has the highest mortality rate, with a 5-year survival rate of only 30% (Vaughan et al., 2011). This is due to the fact that the vast majority of cases are not detected until late-stage, ultimately thwarting attempts to define the cell-of-origin and pathogenesis of this disease.

Although research has traditionally focused on the hypothesis that HGSC arises from the ovarian surface epithelium (OSE) or ovarian inclusion cysts, recent studies suggest that additional

sites of origin exist and a substantial proportion of cases may arise from precursor lesions located in the fallopian tubal epithelium (FTE). The latter hypothesis is based on the detection of early lesions, namely serous tubal intraepithelial carcinomas (STIC), found in the fallopian tubes (FT) of both women at high-risk for developing serous carcinomas as well as patients with disseminated HGSCs (Kindelberger et al., 2007; Lee et al., 2007; Leeper et al., 2002; Levanon et al., 2008; Medeiros et al., 2006; Przybycin et al., 2010). Recent studies of ovarian and tubal tissue samples from high-risk *BRCA1/2* mutation carriers who underwent prophylactic salpingo-oophorectomy procedures to reduce their cancer risk revealed early cancer lesions in ~5%–15% of cases, with 60%–100% of lesions found in the FT fimbria (Leeper et al., 2002; Medeiros et al., 2006). In addition,

Significance

Recent histological studies suggest that many serous carcinomas can arise from intraepithelial lesions in the fallopian tube. This is based largely on association studies and has never been proven due to lack of effective early detection methods in patients and the shortage of valid experimental models. Herein, we present a genetic model of de novo high-grade serous carcinoma (HGSC) that originates in fallopian tubal secretory epithelial cells and recapitulates the key genetic alterations and precursor lesions characteristic of human invasive ovarian cancer. In addition to offering mechanistic insight into the origin and pathogenesis of HGSC, this model provides a platform to explore HGSC sensitivity to therapeutic strategies and to develop better early detection strategies for women at risk.

STIC lesions, which are defined as in situ cancers with *TP53* mutations and increased proliferative capacity, are observed in at least 60% of women with HGSC of the ovary and/or peritoneum (Kindelberger et al., 2007; Przybycin et al., 2010) and similar in situ lesions are not observed in the OSE (Folkins et al., 2008). Such early lesions exhibit shortened telomeres, a notable hallmark of early molecular carcinogenesis (Kuhn et al., 2011; Chene et al., 2013). Clinical observations support the hypothesis that STICs can originate from secretory epithelial cells of the fallopian tube and progress to HGSC by rapidly disseminating to involve ovarian and peritoneal surfaces. This hypothesis is further supported by the shared morphologic and immunophenotypic features of STICs and HGSCs. In addition, injection of transformed primary human FT secretory epithelial cells (FTSECs) into the peritoneum of nude mice induces tumors that grossly, histologically, immunophenotypically, and genomically resemble human HGSCs (Karst et al., 2011a; Jazaeri et al., 2011). However, these associations are largely circumstantial and necessitate experimental proof in order to confirm the role of FTSECs and STICs in serous carcinogenesis. The vast implications of unequivocally establishing a potential cell of origin in HGSC for both cancer prevention and early tumor detection prompted us to develop genetically engineered animal models that mimic human HGSC pathogenesis.

Genetically engineered mouse models for the endometrioid subtype of ovarian cancer have been successfully exploited to resolve the site of origin and pathogenesis for this particular subtype (Dinulescu et al., 2005; Wu et al., 2007, 2013). In contrast, an effective de novo mouse model for HGSC has proven elusive, likely because previous models were designed based on traditional views of ovarian cancer pathogenesis, namely strictly ovarian origin. Previous work has utilized conditional expression of oncogenes (for instance, *Kras*) or conditional deletion of relevant tumor suppressors (such as *Brca1/2*, *Tp53*, *Rb*, and *Pten*); although these markers are well defined in the literature, all have targeted the OSE (Clark-Knowles et al., 2007, 2009; Flesken-Nikitin et al., 2003; Mullany et al., 2011; Quinn et al., 2009; Szabova et al., 2012). Subsequently, some tumors have failed to recapitulate the histology and markers of the human disease (Clark-Knowles et al., 2007, 2009; Mullany et al., 2011; Quinn et al., 2009). Another study utilized an activating *Pik3ca* mutation coupled with *Pten* loss to drive ovarian serous carcinoma from the OSE but this also resulted in granulosa cell and luteoma tumors and did not recapitulate early precursor lesions (Kinross et al., 2012). A recent study targeted deletion of *Pten* and *Dicer*, the ribonuclease essential for the conversion of pre-miRNAs into mature miRNAs, using the anti-Mullerian hormone receptor type 2 promoter to drive Cre expression. Although these animals developed tumors in the FT, they failed to recapitulate the early events of human disease pathogenesis, namely FTSEC transformation and STIC lesions (Kim et al., 2012). Collectively, these studies all suggest that the origin of HGSC is still unknown and may arise from multiple sources. However, developing a genetically engineered mouse model of HGSC, which accurately recapitulates the early alterations and disease progression seen in patients and high-risk women, is key to improving early cancer diagnosis and is an important goal of our study. Such a model can confirm the

transformation continuum from STIC to HGSC and mimic the molecular alterations underlying this process.

RESULTS

PAX8 Is a Marker of the Fallopian Tube Secretory Cell but Not of the Ovarian Surface Epithelium

We have specifically targeted the FTSEC by driving expression of the Cre recombinase from a *Pax8* promoter. PAX8 is a transcription factor that is essential for the development of the female genital tract, including the FTs but not the ovaries (Mittag et al., 2007). In the FTE, PAX8 is a marker of the secretory cell lineage, not the ciliated cell population (Figures 1A and 1B). Consistent with its role as a lineage marker (Bowen et al., 2007; Cheung et al., 2011), PAX8 expression is retained in the FT cells during the process of secretory cell malignant transformation, both in STIC lesions (Figures 1A and 1B) and in the vast majority of HGSCs (Figure 1C) (Laury et al., 2010, 2011; Tacha et al., 2011). In mouse FTE, PAX8 shows a similar pattern of expression in FTSECs and is not present in acetylated tubulin-positive ciliated cells (Figures 1D–1F). Importantly, PAX8 is absent in mouse and human OSE (Figure 1D) (Bowen et al., 2007). This distinct PAX8 expression pattern was confirmed by western blot analysis, which showed strong PAX8 expression in human FTSEC lines and no expression in human ovarian surface epithelial (HOSE) cell lines (Figure 1G).

PAX8 Can Drive Cre Recombinase in the Fallopian Tube Secretory Cell

In order to express Cre recombinase from the mouse FTSEC, we crossed mice expressing the reverse tetracycline-controlled transactivator (*rtTA*) under the control of the *Pax8* promoter (*Pax8-rtTA*) with mice expressing Cre recombinase in a tetracycline-dependent manner (*TetO-Cre*) (Perl et al., 2002; Traykova-Brauch et al., 2008). The combination of both transgenes, which we termed *Pax8-Cre*, was used as a tissue-specific driver for all genetic alterations described hereafter (Figure S1A available online). In order to determine the tissue specificity of the recombination event, *Pax8-Cre* mice were crossed with *Gt(ROSA)26Sor^{tm1Sor}* mice expressing the *loxP-Stop-loxP LacZ* transgene (Figure S1A) (Soriano, 1999). Following administration of doxycycline (Dox, 0.2 mg/ml in drinking water ad libitum) for 14 days to activate Cre-mediated recombination, organs were harvested and subjected to β -galactosidase staining. Gross anatomic inspection showed that the FT exhibited a very strong LacZ staining pattern; some staining was observed in the uterus and, importantly, the ovary was completely negative for LacZ (Figures 1H and 1I). Histologically, as expected from the mosaic pattern of Pax8-positive secretory and Pax8-negative ciliated cells, the FTE exhibited a mosaic pattern of LacZ staining (Figure 1J). Most importantly, microscopic evaluation of the OSE did not exhibit any LacZ staining (Figures S1B and S1C) thereby confirming that HGSC in this model cannot arise from the OSE. As expected, the FTE of *Pax8-rtTA;LSL-LacZ* mice, without *TetO-Cre* (negative control) showed no LacZ staining (Figures S1D and S1E). In addition, endometrial and renal tubular epithelium expressed LacZ (Figures S1F and S1G; Traykova-Brauch et al., 2008), whereas the liver showed focal LacZ staining in scattered hepatocytes (Traykova-Brauch

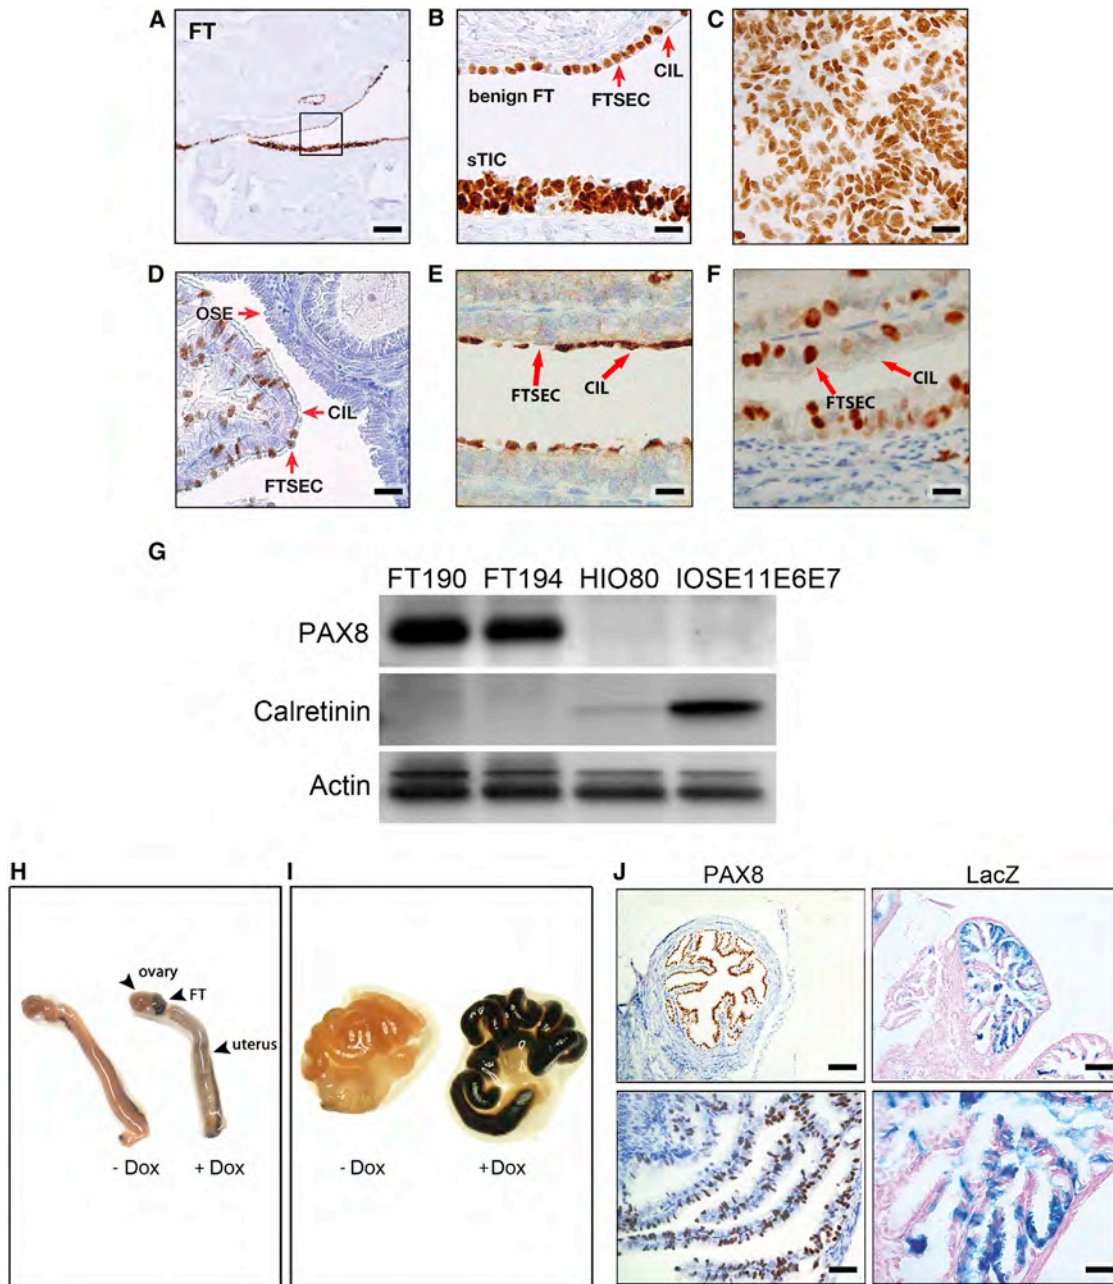

Figure 1. Expression of PAX8, a Specific Müllerian Lineage Marker, during FT Malignant Transformation

(A and B) Immunohistochemistry (IHC) for PAX8 in the human FTE is shown for the benign epithelium (top) and STIC (bottom). The square area in (A) is shown at a higher magnification in (B). PAX8 positive FTSEC and PAX8-negative ciliated cells (CIL) are demarcated by red arrows.

(C) IHC for PAX8 in human HGSC.

(D) PAX8 expression in mouse OSE, CIL cells, and FTSECs.

(E) IHC for acetylated tubulin in mouse CIL cells and FTSEC.

(F) PAX8 expression in murine nonciliated FTSECs.

(G) PAX8 and calretinin expression in immortalized FTSEC lines (FT190 and FT194) and in HOSE cell lines (HIO-80 and IOSE11E6E7) as depicted by western blot analysis. Calretinin is used as a marker for HOSE and β -actin serves as a loading control.

(H) Gross anatomy of murine female genital tracts collected from *Pax8-rtTA;TetO-Cre;LSL-LacZ* mice treated (+Dox) or untreated (–Dox) with Dox and stained with a β -galactosidase stain.

(I) Higher magnification of the FT treated or untreated with Dox.

(J) Non-neoplastic mouse FTE stained with PAX8 or LacZ as indicated.

Scale bars represent 500 μ m (A), 50 μ m (B–F), 100 μ m (J, top subpanels), and 33.3 μ m (J, bottom subpanels). See also [Figure S1](#).

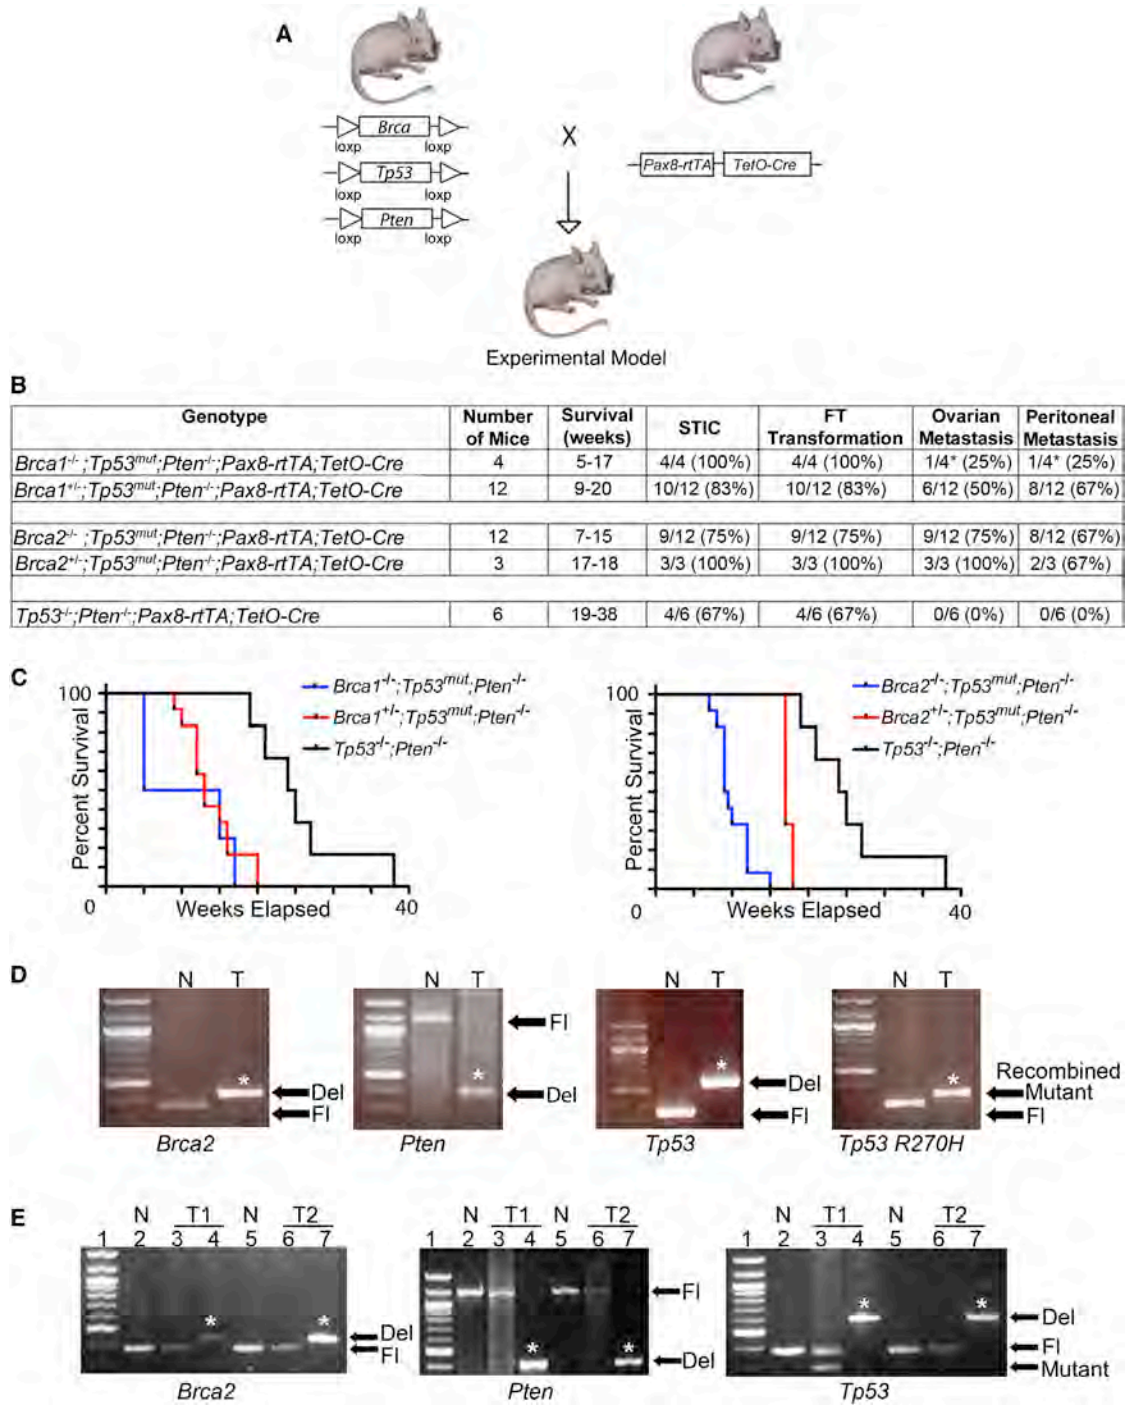

Figure 2. The Role of *Brca*, *Tp53*, and *Pten* Genetic Alterations in the Development of STIC, HGSC, and Tumor Metastases in *Pax8-Cre* Mice (A) Schematic representation of conditional *Brca1*, *Brca2*, *Tp53*, *Pten* alleles, and *Pax8-rtTA;TetO-Cre* recombination.

(B) Summary of the phenotypic characteristics of the five *Pax8-Cre* cohorts: *Brca1^{-/-};Tp53^{mut};Pten^{-/-}*, *Brca1^{+/-};Tp53^{mut};Pten^{-/-}*, *Brca2^{-/-};Tp53^{mut};Pten^{-/-}*, *Brca2^{+/-};Tp53^{mut};Pten^{-/-}*, and *Tp53^{-/-};Pten^{-/-}* mice. The asterisk (*) denotes that two of the four *Brca1^{-/-};Tp53^{mut};Pten^{-/-}* mice had to be sacrificed earlier at 5 weeks due to unrelated skin lesions in accordance to veterinarian recommendations, and as a result did not have time to develop metastatic disease. The *Brca1^{-/-};Tp53^{mut};Pten^{-/-}* cohort includes two *Brca1^{-/-};Tp53^{-/-};Pten^{-/-}* and two *Brca1^{-/-};Tp53^{R270H};Pten^{-/-}* mice. The *Brca1^{+/-};Tp53^{mut};Pten^{-/-}* cohort includes eight *Brca1^{+/-};Tp53^{-/-};Pten^{-/-}* and four *Brca1^{+/-};Tp53^{R270H};Pten^{-/-}* animals. The *Brca2^{-/-};Tp53^{mut};Pten^{-/-}* cohort includes six *Brca2^{-/-};Tp53^{-/-};Pten^{-/-}* and six *Brca2^{-/-};Tp53^{R270H};Pten^{-/-}* mice. The *Brca2^{+/-};Tp53^{mut};Pten^{-/-}* cohort includes two *Brca2^{+/-};Tp53^{-/-};Pten^{-/-}* and one *Brca2^{+/-};Tp53^{R270H};Pten^{-/-}* animals.

(C) Kaplan-Meier analysis of overall survival of all mouse cohorts. $p < 0.01$ comparing with and without deletion of any alleles of *Brca1* or *Brca2*. Statistical analysis was calculated using a log-rank analysis.

(legend continued on next page)

et al., 2008). As previously shown, the thyroid, another PAX8-expressing organ, does not express *rtTA* in this *Pax8-rtTA* mouse strain (Traykova-Brauch et al., 2008) and was negative for LacZ expression (Figures S1H and S1I). No other organs displayed LacZ staining.

Murine cohorts were generated harboring *Pax8-Cre* driven inactivation of different combinations of the *Brca* (*Brca1* or *Brca2*), *Tp53* (loss of function and/or dominant negative inactivating *R270H* mutation), and *Pten* genes, which are commonly altered in ovarian cancer patients (Figures 2A–2D) (Cancer Genome Atlas Research Network, 2011). Heterozygous and homozygous *Brca1* (and *Brca2*) mutants (mut), unless otherwise indicated, will collectively be designated *Brca1^{mut}* (*Brca2^{mut}*) as they yielded similar tumor phenotypes. Similarly, *Tp53^{-/-}* gave similar results as *Tp53^{R270H/-}* and therefore are collectively designated *Tp53^{mut}*. The Kaplan-Meier curves of the five *Pax8-rtTA;TetO-Cre* murine cohorts, *Brca1^{-/-};Tp53^{mut};Pten^{-/-}*, *Brca1^{+/-};Tp53^{mut};Pten^{-/-}*, *Brca2^{-/-};Tp53^{mut};Pten^{-/-}*, *Brca2^{+/-};Tp53^{mut};Pten^{-/-}*, and *Tp53^{-/-};Pten^{-/-}* mice are shown for comparison in Figure 2C. Interestingly, we noticed a statistically significant increase in disease latency in the *Tp53^{-/-}; Pten^{-/-}* cohort in comparison to either *Brca1^{mut};Tp53^{mut};Pten^{-/-}* or *Brca2^{mut};Tp53^{mut};Pten^{-/-}* mice ($p < 0.01$, Figure 2C). Furthermore, the survival of *Brca2^{-/-}* mice was significantly lower when compared to *Brca2^{+/-}* mice ($p < 0.05$, Figure 2C). Otherwise, the heterozygous and homozygous *Brca1* and *Brca2* animals yielded similar phenotypic results. Evidence of *Brca2*, *Tp53*, and *Pten* recombination in our animal models is shown in Figure 2D whereas the efficiency of recombination events at the three genetic loci is displayed in Figure 2E. Tumors that show incomplete recombination likely reflect the presence of stromal and/or ciliated epithelial cells that are not targeted. In patients, *BRCA1* and *BRCA2* are known to be associated with hereditary breast and ovarian cancer. In the recently published Cancer Genome Atlas Research Network (TCGA) data, *BRCA1* and *BRCA2* show germline mutations in 9% and 8% of HGSC cases, respectively, and somatic mutations in an additional 3% of cases (Cancer Genome Atlas Research Network, 2011). In addition, *BRCA1* and *BRCA2* germline mutation frequency is as high as 17% of cases in a large series of Australian HGSC patients (Alsop et al., 2012). In addition, *TP53* is mutated in the vast majority (96%) of human HGSC cases. Furthermore, according to the TCGA data, although homozygous loss of *PTEN* is seen in only 7% of ovarian cancer cases, the PI3K/PTEN pathway is aberrant in 74.4% of HGSC cases (Figure S2). More specifically, TCGA analysis shows combined alterations, including mutations, single and/or double copy deletions of *BRCA1*, *TP53*, and *PTEN* to be prevalent in 31% of cases, with homozygous loss of *PTEN* being present in 8% of cases harboring *BRCA1;TP53* alterations (Table S1). A similar TCGA analysis for *BRCA2* reveals coexisting

alterations, including mutations, single and/or double copy deletions of *BRCA2*, *TP53*, and *PTEN* in 25% of cases, with homozygous *PTEN* loss being present in 7% of *BRCA2;TP53* altered cases (Table S2). Therefore, alterations in *BRCA1/2*, *TP53*, and *PTEN* genes serve as a relevant model for human FT transformation and development of HGSC in patients.

***Pax8*-Driven Deletions of *Brca*, *Tp53*, and *Pten* Lead to Development of HGSCs Arising from FTSECs**

Cre-mediated recombination in both *Brca1^{mut};Tp53^{mut};Pten^{-/-}* and *Brca2^{mut};Tp53^{mut};Pten^{-/-}* mice led to development of HGSCs following Dox administration. In contrast to a normal murine FT (Figure 3A), Dox-activated FTs underwent transformation marked by secretory cell proliferation, loss of polarity, cellular atypia, and serous histology, all consistent with STIC (Figures 3B–3D; data not shown). In all invasive carcinomas that metastasized to the ovary and peritoneum, the histology was characteristic of HGSC (Figures 3E–3H; data not shown). HGSC tumors metastasized to the ovary in 7 of 16 *Brca1^{mut};Tp53^{mut};Pten^{-/-}* and 12 of 15 *Brca2^{mut};Tp53^{mut};Pten^{-/-}* mice (Figure 3F; data not shown). In 5 of 16 *Brca1^{mut};Tp53^{mut};Pten^{-/-}* and 3 of 15 *Brca2^{mut};Tp53^{mut};Pten^{-/-}* mice, the tumor metastasized to the liver (Figure 3G; data not shown) and in 9 of 16 *Brca1^{mut};Tp53^{mut};Pten^{-/-}* and 10 of 15 *Brca2^{mut};Tp53^{mut};Pten^{-/-}* mice, the tumor metastasized to the peritoneal cavity (Figures 3E and 3H; data not shown). Although the omentum was typically involved, peritoneal involvement was generally widespread, and we did not discern between the different organs involved or the omentum. These findings are consistent with the pattern of HGSC spread in humans. Frequent ovarian metastases are of special interest because HGSC is commonly diagnosed in the ovary. Immunohistochemical analysis of murine preinvasive and invasive lesions demonstrated a high degree of concordance between human and mouse tumor markers (Figure 3I). Thus, PAX8 serves as the hallmark for human HGSC diagnosis. In line with our *Pax8*-driven model, murine preinvasive lesions and invasive tumors were PAX8 positive, similar to human counterparts (Figure 3I). As expected, all murine tumors with dominant negative *Tp53 R270H* mutations showed accumulation of nuclear TP53 immunoreactivity (Figure 3I); in addition, an increased Ki-67 proliferative index was seen in STICs and metastatic lesions (Figure 3I). Thus, the immunohistochemical profiles of murine tumors mimic those of human STICs and HGSC tumors and confirm our targeting strategy. Furthermore, in addition to being positive for PAX8 and Ki-67, murine STIC lesions showed immunoreactivity for Stathmin-1 (STMN1) (Figures 4A–4D) in contrast to normal FTE (located adjacent to the STIC, left side of the image, in Figures 4C and 4D). STMN1 is a marker for early human serous carcinoma that is significantly increased upon progression to STIC and invasive carcinoma in patients (Karst et al., 2011b). As expected,

(D) PCR reaction illustrating *Cre*-mediated recombination of *Brca2*, *Pten*, and *Tp53* alleles. T, DNA isolated from a *Brca2^{-/-};Tp53^{R270H/-};Pten^{-/-}* HGSC tumor; N, unrecombined DNA; FI, unrecombined floxed alleles; Del, deleted alleles; Mutant, *Tp53^{R270H}* allele. The asterisk (*) denotes recombined (deleted or mutant) bands.

(E) Efficiency of *Cre*-mediated recombination for *Brca2*, *Pten*, and *Tp53* alleles, respectively, in HGSC tumors isolated from *Brca2^{-/-};Tp53^{R270H/-};Pten^{-/-}* (T1) and *Brca2^{-/-};Tp53^{-/-};Pten^{-/-}* (T2) mice as assayed by PCR. Lanes 2 and 5 (N) indicate control unrecombined DNA, lanes 3 (T1) and 6 (T2) indicate the level of unrecombined DNA in tumor cells, and lanes 4 (T1) and 7 (T2) show the level of recombined DNA in tumors. The asterisk (*) denotes recombined (deleted) bands. See also Figure S2 and Tables S1 and S2.

(A) Cross-section of normal FT from a control wild-type mouse.
 (B and C) Examples of *Brca2*^{-/-};*Tp53*^{R270H/-};*Pten*^{-/-} STICs.
 (D) Gross anatomy of a *Brca2*^{+/-};*Tp53*^{R270H/-};*Pten*^{-/-} HGSC originating in the fallopian tube (FT) and metastasizing to the ovary (circled, OvT). Uterus (Ut) is shown as a reference.
 (E) Representative pictures of disseminated intraperitoneal *Brca2*^{+/-};*Tp53*^{R270H/-};*Pten*^{-/-} tumors.
 (F) Representative pictures of metastases from *Brca2*^{+/-};*Tp53*^{R270H/-};*Pten*^{-/-} HGSCs to the ovarian cortex in close proximity to the ovarian stalk. Tumor border is marked by arrowheads.
 (G) Examples of metastases from *Brca2*^{+/-};*Tp53*^{R270H/-};*Pten*^{-/-} tumors to the liver.
 (H) Gross anatomy of a *Brca2*^{+/-};*Tp53*^{R270H/-};*Pten*^{-/-} HGSC tumor originating in the fallopian tube (FT) and metastasizing to the peritoneal cavity (circled, T).
 (I) Comparative study of representative examples of murine *Brca2*^{+/-};*Tp53*^{R270H/-};*Pten*^{-/-} tumor lesions and human STICs and HGSCs. Tissue sections were stained with H&E or stained for TP53, PAX8, or Ki-67, as indicated.
 Scale bars represent 200 μ m (A, B, and F), 50 μ m (C and I as shown in mouse STIC IHC, mouse HGSC, and human STIC subpanels), and 100 μ m (E, G, and I as shown in mouse STIC H&E and human HGSC subpanels).

tumors were positive for epithelial markers, including Pan-Keratin and CK8 (Figure 5A). In addition, PAX8-immunoreactive tumors and metastases were also positive for either PAX2 (Figure 5B) or WT-1 (Figure 5C), two markers that are expressed by human HGSCs. As noted earlier, the endometrium expresses *Pax8* and this expression was confirmed with LacZ staining (Figures S1F and S1G). Because *PTEN* is the most common

genetic alteration observed in endometrial neoplasms (Mutter et al., 2000), we closely examined the endometrium in all cohorts of mice. All mice had various degrees of endometrial changes, which recapitulated human endometrial hyperplasia, dysplasia, or carcinoma (Figure S3A). Interestingly, intrauterine endometrial lesions were negative for PAX2 and WT1 markers (Figures S3B and S3C), whereas the STICs and metastatic

Figure 4. STMN1 Expression in Murine STIC Lesions

(A and B) Representative low (A) and high (B) magnification images of immunohistochemical analysis for PAX8, Ki-67, and STMN1 markers in murine *Brca2*^{-/-};*Tp53*^{-/-};*Pten*^{-/-} STIC lesions.

(C and D) Representative low (C) and high (D) magnification images of immunohistochemical analysis for PAX8, Ki-67, and STMN1 in early murine *Brca2*^{-/-};*Tp53*^{-/-};*Pten*^{-/-} tumor STIC lesion in the distal FT. Normal distal tube (fimbria) can be seen on the left side of the image.

Scale bars represent 100 μ m (A and C) and 50 μ m (B and D).

HGSC tumors (described above) retained PAX2 expression (Figure S3B) or WT1 expression (Figure S3C), strongly suggesting that the metastatic lesions arose from the FT and not the endometrium.

In order to study the contribution of *Brca* and *Pten* genetic alterations to the pathogenesis of HGSC tumors, we generated control cohorts of *Tp53*^{-/-};*Pten*^{-/-} mice without *Brca* alterations and *Brca2*^{-/-};*Tp53*^{mut} mice without *Pten* alterations, respectively. Interestingly, the *Tp53*^{-/-};*Pten*^{-/-} mice did not progress past the preinvasive stage of the disease. Four of six *Tp53*^{-/-};*Pten*^{-/-} mice had tubal transformation and developed STICs at the time of sacrifice (19–38 weeks), but none showed

invasive tumors, suggesting that *Brca1* or *Brca2* gene alterations are necessary for the progression of ovarian and peritoneal HGSCs (Figures 2B and 2C). Although the *Tp53*^{-/-};*Pten*^{-/-} cohort did not develop invasive HGSC, four of six mice had to be sacrificed according to veterinary recommendation because of palpable uterine tumors or a visible reduction in body condition, scruffy appearance, and hair loss (at 24 and 38 weeks, respectively), which required euthanasia. Histopathological analysis of the *Tp53*^{-/-};*Pten*^{-/-} mice with uterine tumors showed locally enlarged endometrial tumors but no metastases were detected. The remaining *Tp53*^{-/-};*Pten*^{-/-} mice had to be euthanized due to unrelated conditions (i.e., one of six mice

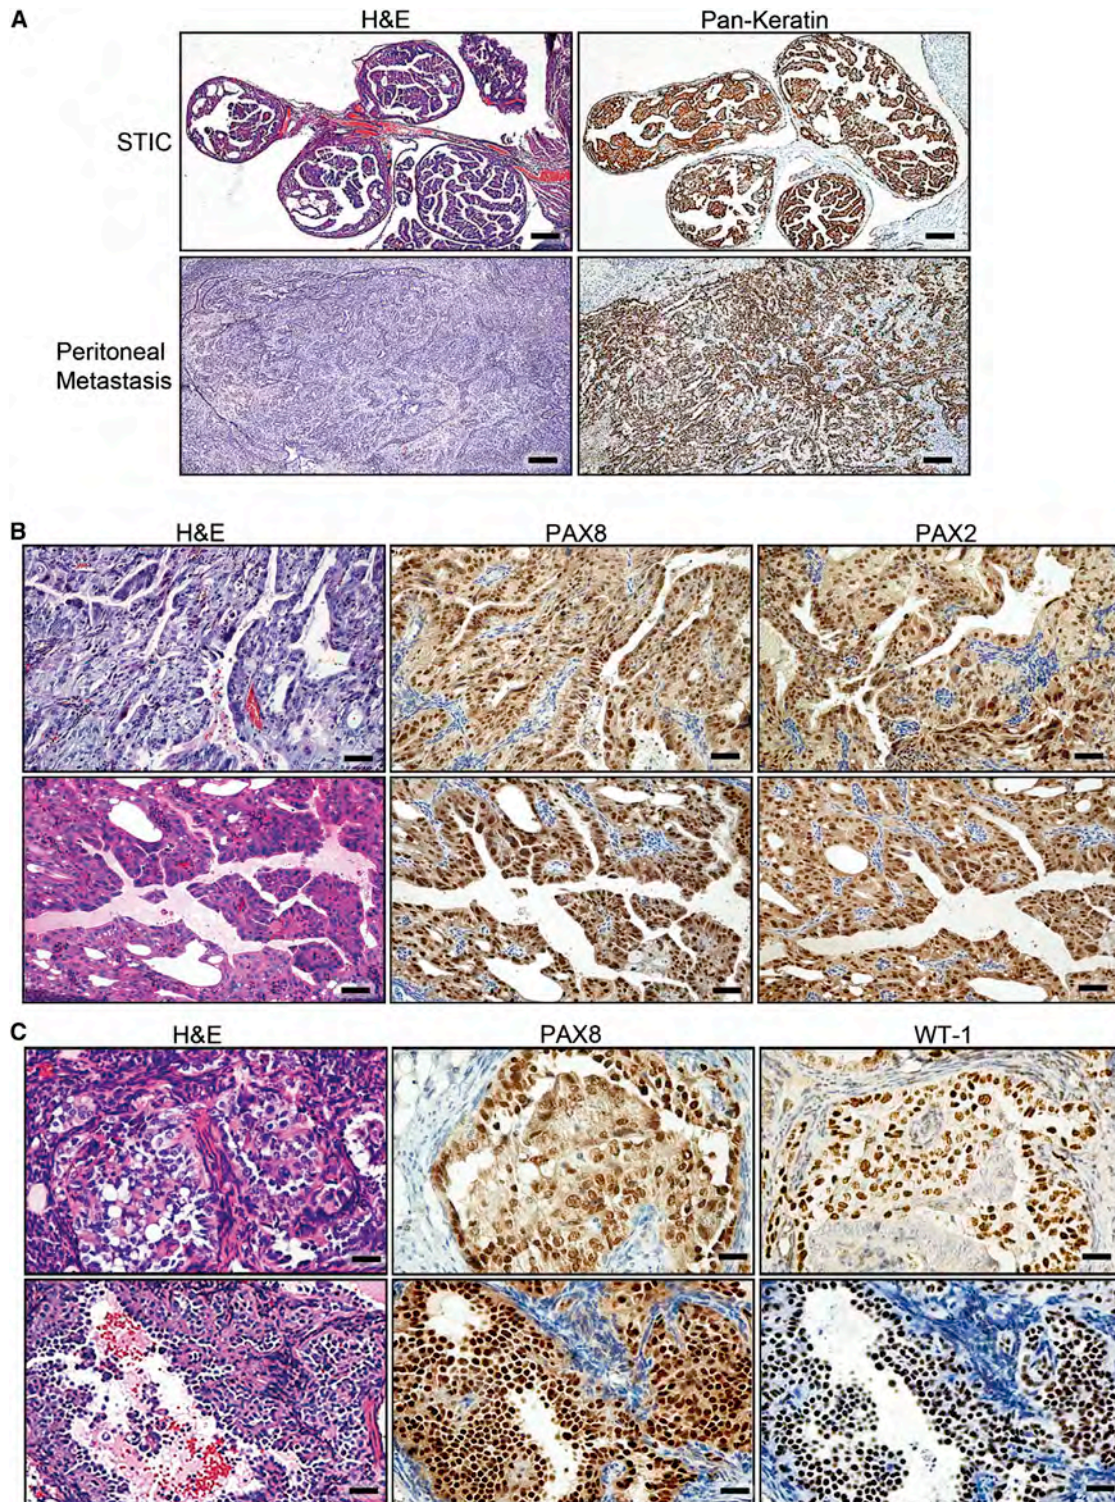

Figure 5. Immunohistochemical Analysis for Epithelial and HGSC Markers in Murine Serous Tumors

(A) Staining of STICs and invasive tumors for Pan-Keratin in *Brca1^{+/+};Tp53^{-/-};Pten^{-/-}* tumors.

(B) Examples of PAX8 and PAX2 staining in *Brca1^{+/+};Tp53^{-/-};Pten^{-/-}* tumor lesions metastatic to the ovary.

(C) Representative examples of PAX8 and WT1 staining in *Brca2^{-/-};Tp53^{R270H/-};Pten^{-/-}* tumor lesions metastatic to the ovary.

Scale bars represent 500 μm (A), 100 μm (B), and 50 μm (C). See also Figure S3.

developed malocclusion and one of six developed a large skin abrasion). Furthermore, in *Brca2*^{-/-};*Tp53*^{mut} mice, in which *Pten* is wild-type, the disease latency was much longer (30–43 weeks) and tumorigenesis was inefficient (only 3 of 11 mice developed peritoneal metastases), suggesting that additional genes are needed to cooperate with *Brca* and *Tp53* deletion or mutation to induce tumor initiation and progression. Interestingly, STICs were difficult to detect in the *Brca2*^{-/-};*Tp53*^{mut} mice because invasive disease was widely present at the time that the animals were sacrificed, a not uncommon phenomenon in human HGSC. This, in part, can explain why STIC lesions are not identified in 100% of HGSCs. More importantly, these results suggest that loss of *Pten* or activation of the PTEN/PI3K pathway is necessary for efficient tumor development and STIC formation in the murine oviduct. Similarly, a recent patient study indicated that PTEN expression was markedly reduced or absent in one-third of human STICs (Roh et al., 2010).

Salpingectomies, Oophorectomies, and Hysterectomies in Pax8-Driven BRCA Models Support a Tubal Origin for HGSC

In order to further rule out the endometrial origin of HGSC metastases in our mice, we performed hysterectomies and salpingectomies in *Brca1*^{mut};*Tp53*^{mut};*Pten*^{-/-} and *Brca2*^{mut};*Tp53*^{mut};*Pten*^{-/-} murine cohorts. Uterus removal by hysterectomy resulted in STICs and tubal transformation in all mice, ovarian HGSC invasion in three of six mice and peritoneal HGSC metastases in five of six animals at 9–12 weeks post-Cre induction (Figures 6A–6F; Figure S4A). Immunohistochemical and pathological analysis of STICs and ovarian/peritoneal tumor metastases in the hysterectomy cohort was consistent with HGSC profiles (Figure 6F). Invasive tumors were positive for human epithelial and HGSC markers, such as CK8, PAX8, WT1, and TP53 (Figure 6F). In contrast, FT removal by salpingectomy resulted in absence of HGSC in all mice and no metastases (Figures S4A–S4C). Interestingly, removal of the ovary resulted in generation of STICs and tubal transformation in all mice but reduced peritoneal metastasis, suggesting that the ovary induces a permissive environment for advanced disease, possibly through the role of ovarian hormones or through a mechanism that promotes metastatic spread (Figures S4A–S4D). It is possible that the ovaries are preferential sites of early metastatic disease and facilitate growth or they produce hormones that encourage peritoneal spread. However, because we sacrificed the oophorectomized cohort within a similar timeline as our intact ovary animals, we cannot rule out that the development of metastatic disease in these mice may necessitate longer times than the timeline we studied.

PAX8-Driven Tumors Show Human HGSC Biomarkers and Genomically Correlate with Human TCGA Data

Serum was collected and tested for the presence of CA-125, the best characterized serum biomarker for human HGSC (Bast, 2003). All mice showed significantly higher CA-125 levels than control mice (Figure 7A). To prove that the elevated CA-125 biomarker detected in the bloodstream is originating from HGSCs, CA-125 was further assessed in tumor samples using western blot analysis. As expected, tumor samples showed increased levels of CA-125 in comparison to control murine

FTs (Figure 7B). In addition, western analysis of tumor samples showed increased γ H2A.X expression in murine HGSCs in comparison to normal FT, supporting our previous report that the transformation process of FTSEC to HGSC is characterized by the acquisition of abundant DNA damage (Figure 7B) (Levanon et al., 2008).

We further performed a genomic copy number analysis of HGSC tumors isolated from *Brca2*^{-/-};*Tp53*^{mut};*Pten*^{-/-} mice using array comparative genomic hybridization (aCGH) studies (Figure 7C). The analyzed tumors showed the presence of a large number of genomic copy number alterations, including recurrent alterations (Figure 7C), similar to the abundance of copy number alterations recently reported in human HGSCs (Cancer Genome Atlas Research Network, 2011). In order to compare the regions of copy number alterations in the mouse HGSC model with those seen in patients, we performed orthology mapping and correlated the syntenic regions with recurrent alterations reported by TCGA, using the cBio portal (<http://www.cbioportal.org>) (Cerami et al., 2012; Cancer Genome Atlas Research Network, 2011). Interestingly, array CGH analysis revealed several genomic alterations in the mouse models that correlated with significant copy number alterations in the human TCGA data set (Table 1; Tables S3–S5). This overlap was found to be statistically significant ($p < 0.001$) by random permutation analysis (Figure S5). This analysis also identified multiple syntenic regions that overlapped with the top 20 significant recurrent alterations from the TCGA data set (Table 1; Table S6). *C-MYC* and *KRAS*, among the top recurrent amplifications in the TCGA data set, were also amplified in our murine models with *Kras* showing recurrent amplifications in two of the three mouse models. We also found many alterations in genes that mapped to pathways reported by TCGA, namely DNA damage (*ATM*, *RAD17*), DNA repair and HR-mediated repair (*ATM*, *TEX15*, *PALB2*, *FANCC*, *TERT*), FOXM1 cell cycle pathway (*FOXM1*, *SKP2*), NOTCH pathway (*KRT1*, *PPARG*, *NUMB*, *SEL1*), RAS/MAPK signaling (*KRAS*, *MAPK15*), RB pathway (*E2F7*), and PI3K/MYC (*PIK3R1*, *FOXO3*, *RICTOR*, *c-MYC*) signaling, respectively (Table 1; Figure S6; Tables S3–S6) (Cancer Genome Atlas Research Network, 2011). Other significant recurrently TCGA altered genes that were also detected in the mouse tumors included tumor suppressor genes (*APC2*, *WWOX*, *ANKRD11*, *INPP4B*), as well as *A2M*, *POLK*, and *CDK7* (Table 1; Tables S5 and S6). Interestingly, large regions of aneuploidy were seen to harbor genes that are syntenic to cancer-related genes in patients, such as *APC2*, *CDH1*, *PIK3R1*, *MAPK15*, and *INPP4B*. Importantly, *INPP4B* is emerging as a credible tumor suppressor gene in both ovarian and breast cancers. Loss of heterozygosity at *4q31.21*, the chromosomal region containing the *INPP4B* gene occurs in up to 60% of *BRCA1* mutant and triple-negative/basal-like breast carcinomas and 39.8% of ovarian cancer cases (Gewinner et al., 2009; Bertucci and Mitchell, 2013). Furthermore, reduced *INPP4B* protein expression correlates with decreased overall patient survival for both breast and ovarian cancers (Gewinner et al., 2009; Bertucci and Mitchell, 2013). In summary, genomic analysis revealed that the alterations seen in the murine models are similar to those observed in human tumors, indicating that these models successfully recapitulate the genomic alteration profile of human HGSCs.

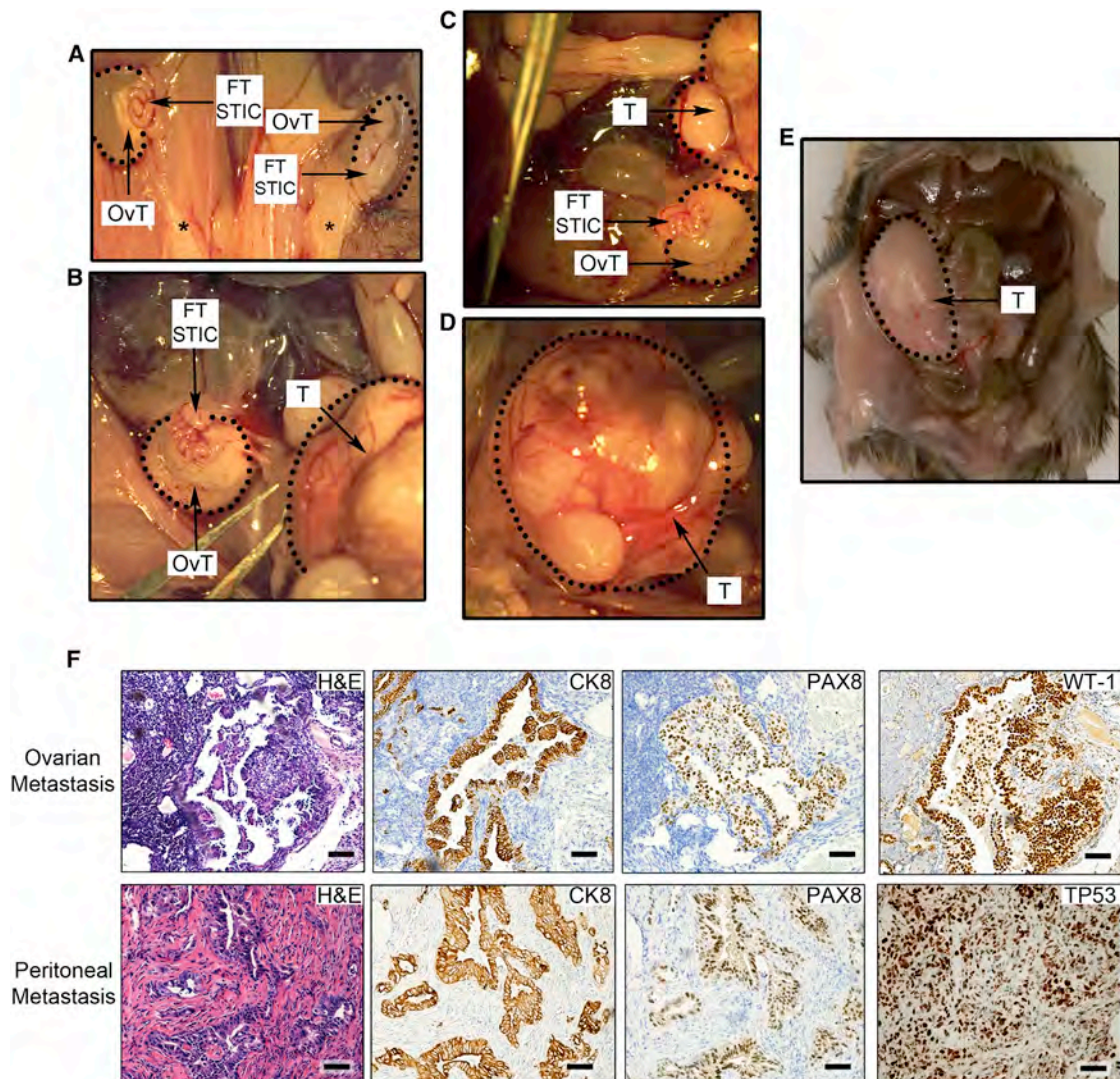

Figure 6. Hysterectomy, Salpingectomy, and Oophorectomy Experiments to Assess the Origins of HGSCs

(A–E) Representative gross anatomy of tumor lesions found in mice undergoing hysterectomy. (A) Impact of hysterectomy on the development of bilateral ovarian HGSC tumors (OvT) originating in the fallopian tube (FT STIC) in a *Brca2*^{-/-}; *Tp53*^{R270H/-}; *Pten*^{-/-} mouse. Black stars denote the removal of the uterus and the presence of the remaining fat deposits. FT STICs denote grossly normal appearing but histologically transformed fallopian tubes containing preinvasive lesions. (B–D) Hysterectomy in a second *Brca*^{+/-}; *Tp53*^{-/-}; *Pten*^{-/-} mouse and the resultant HGSC metastasis to the ovary (encircled OvT) and peritoneum (encircled T).

(D) The image depicts a higher magnification of the peritoneal HGSC metastasis (T).

(E) Abdominal HGSC metastases (T) in a third *Brca2*^{-/-}; *Tp53*^{R270H/-}; *Pten*^{-/-} mouse following hysterectomy.

(F) Histopathological and immunohistochemical (CK8, PAX8, WT1, and TP53) analysis of ovarian (top subpanels) and peritoneal (bottom subpanels) HGSC metastases in murine models that underwent hysterectomy. Scale bars represent 100 μm.

See also Figure S4.

DISCUSSION

Resolving the site of origin for high-grade serous ovarian carcinomas is integral to devising optimal strategies for risk reduction in high-risk women (Collins et al., 2011). Similarly, determining precisely where these tumors initiate will influence strategies for early detection. This includes the development of screening tests using novel serum tumor markers and improved methods of diagnostic imaging that focus on the distal FTE, in addition to the ovary. However, achieving these goals requires a model

that accurately mimics the human disease. Although several animal models of ovarian cancer have recently been reported, none target the clinically relevant FTSEC. One recent study suggests that stem cells in the ovarian hilum and at the junction between OSE, mesothelium, and FT epithelium may be more susceptible to transformation; however, to date, there is no clinical evidence of transformation and human precursor lesions occurring in this area (Flesken-Nikitin et al., 2013). In this study, we successfully generated a de novo mouse model of HGSC that targets commonly altered HGSC genes

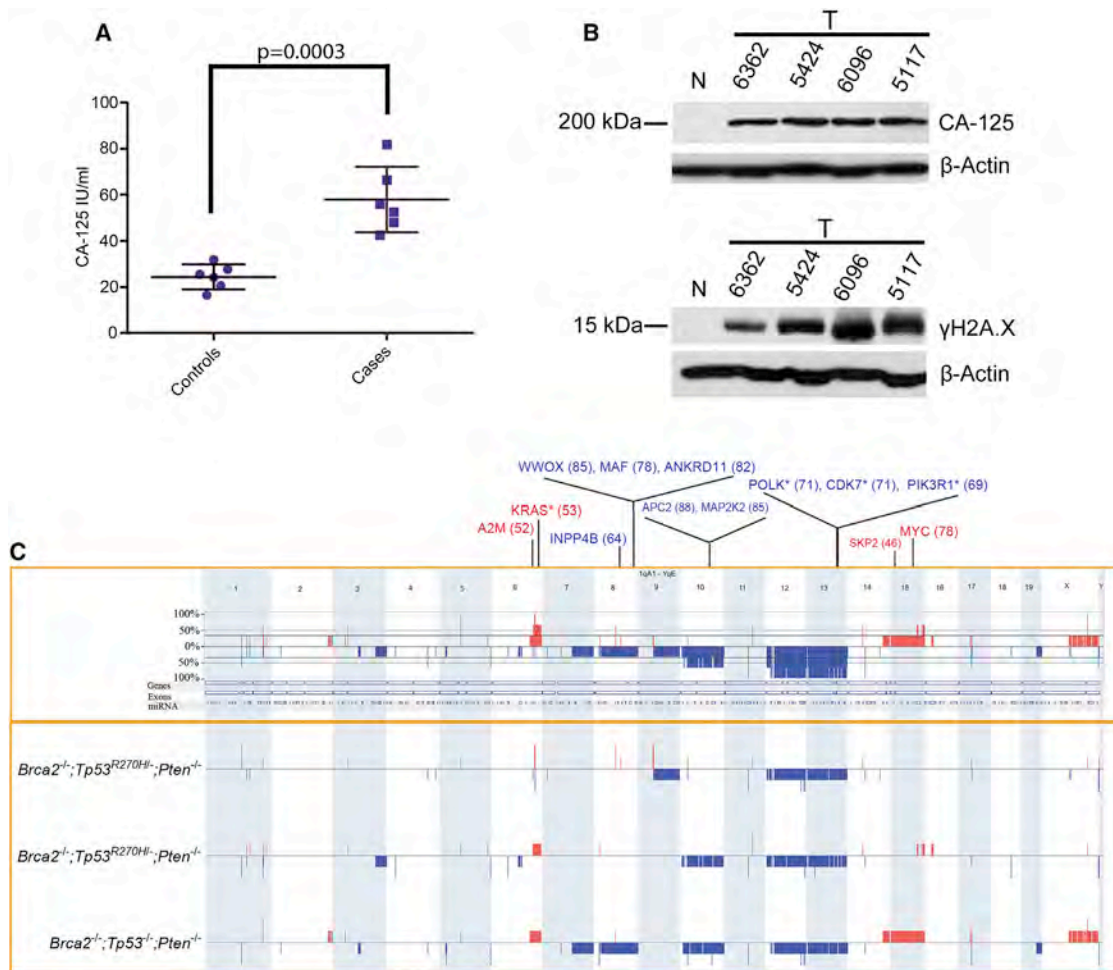

Figure 7. Serologic and Genomic Analyses of Tumors from Genetically Engineered Models

(A) Serum CA-125 levels in tumor-bearing mice (cases) compared to control animals. P value was calculated using a two-tailed student's t test. Error bars represent SD.

(B) Western blot analysis for CA-125 and γ H2A.X levels in four tumor samples isolated from *Brca1*^{+/-};*Tp53*^{-/-};*Pten*^{-/-} (#6362 and #5424) and *Brca2*^{-/-};*Tp53*^{R270H/-};*Pten*^{-/-} mice (#6096 and #5117) and compared to normal Dox-untreated FT (N).

(C) Schematic representation of the genomic alterations found in murine HGSCs. Copy number losses and gains are shown in blue and red, respectively. The boxed upper panel depicts the frequency of the alterations including all murine tumors tested, while the boxed lower panel represents the alterations found in individual tumors. Key orthologous genes, which show high frequency alterations in the TCGA data set, are also indicated, with losses in blue and gains in red. The number within parenthesis indicates the percentage of samples bearing the given alteration in TCGA (single copy alterations). The asterisk indicates genes that are recurrently altered in mouse models.

specifically to secretory epithelial cells within the fallopian tube. Interestingly, when using the *Pax8* promoter to drive *Cre*-mediated recombination of *Brca1* or *Brca2*, *Tp53*, and *Pten* in FTSECs, we observe the development of precursor STIC lesions, HGSC, and the progression to advanced stage disease, including ovarian and peritoneal metastases. By targeting genes that are commonly altered in human HGSC (Cancer Genome Atlas Research Network, 2011), we have generated a murine model system that is highly clinically relevant.

To date, although it is still unclear if we can define a single cell of origin for HGSCs, our models serve as a proof-of-concept that high-grade serous “ovarian” tumors can arise from FTSECs and progress to metastatic disease via preinvasive lesions, namely

STICs. Interestingly, despite the fact that the mice displayed STIC lesions, the FT appeared normal on gross inspection in the majority of cases, whereas the ovary often showed visible signs of disease. This observation is made repeatedly in the examination of human specimens and may shed light on the propensity to term this disease “ovarian” cancer. Importantly, the ability of our murine tumors to accurately recapitulate the histologic, immunophenotypic, and genomic alterations observed in human HGSC, provides a compelling argument for serious carcinogenesis originating in the FTSEC. Specifically, the tumors expressed key tumor and serum proteins, including CK-8, STMN1, PAX2, P53, Ki-67, WT1, and CA-125, all of which are used clinically in the assessment of ovarian tumors. In addition,

^dGene is one of the top 20 significant genes in the TCGA data set.

our genomic analysis revealed that the alterations seen in murine tumors are indeed similar to those observed in corresponding HGSC patients (Cancer Genome Atlas Research Network, 2011), such as amplifications of the *c-Myc* locus, and copy number alterations in DNA damage, HR-mediated repair, Notch, PI3K/KRAS, and cell-cycle-related genes, indicating that these models faithfully recapitulate human HGSC pathogenesis.

TP53 mutations are one of the hallmarks of HGSC (Cancer Genome Atlas Research Network, 2011; Ahmed et al., 2010) and widely disseminated disease is likely to harbor dominant negative and/or loss of function mutations at the *TP53* locus (Sood et al., 1999). However, although *TP53* mutations appear to be obligatory in HGSC, to date, little is known about the ability of *TP53* to drive ovarian cancer. In our models, there was no obvious phenotypic difference between tumors with complete deletion of *TP53* and tumors expressing a *TP53*^{R270H} dominant negative mutation. Interestingly, *TP53* mutations coupled with loss of *Pten* did not drive progression of the disease beyond the initial preinvasive stage in our mice, even well beyond the timeline when we saw widespread peritoneal disease with the additional targeting of *Brca1* or *Brca2*. This observation supports clinical data that *TP53* mutations alone rarely drive ovarian tumor formation (Nichols et al., 2001) but suggests that *PTEN* loss, a frequent occurrence in human STICs (Roh et al., 2010), can cooperate with mutant *TP53* in early serous tumori-

genesis. Future studies will focus on understanding the clinical implications of *TP53* loss versus expression of various different *TP53* mutants in the development of HGSC. Collectively, the murine and human data indicate that alterations in *PTEN* or the *PTEN*/*PI3K* pathway are important in the development of STIC lesions and FTSEC malignant transformation. Furthermore, our data suggest that the *BRCA* status may play a much more significant role in the development of metastatic HGSC despite it being altered much less frequently than *TP53* in human HGSC cases (Alsop et al., 2012; Cancer Genome Atlas Research Network, 2011). Previous studies have shown that cells with loss of expression in *BRCA1* or *BRCA2* genes have defective HR-mediated repair pathways and are likely candidates for PARP inhibitors (Farmer et al., 2005; Fong et al., 2009; Veeck et al., 2010). It has recently been suggested that other genetic alterations, including *EMSY* mutations, deletion or mutation of *PTEN* and *INPP4B* genes, *ATM* or *ATR* mutations, and Fanconi anemia gene mutations, may render cells sensitive to PARP inhibition; however, this has not been tested in an experimental *in vivo* model. Our models, which have shown many of these genetic alterations, allow for an elegant system in which to test the efficacy of PARP inhibitors. Furthermore, these models will allow us to investigate in a preclinical setting whether tumors with *BRCA2* mutations have a more efficacious response to PARP inhibitors compared to *BRCA1* tumors.

Most importantly, early detection of HGSC is difficult but the concept is highly attractive because it can conceivably be achieved at less cost and burden to the patient. If a significant proportion of “ovarian” serous cancers actually emerge from the distal fallopian tube, a significant shift in both conceptual thinking and preventive strategy will be required. It will be important to determine if patients at high-risk for HGSC should only have the affected distal portion of the fallopian tube removed, rather than both tubes and ovaries. Can these young *BRCA* women be offered risk-reduction surgery without undergoing surgical menopause and loss of their fertility? Similarly, determining precisely where these tumors initiate will influence strategies for early detection. This includes the development of screening tests using novel serum tumor markers and improved methods of diagnostic imaging that focus on the distal FTE in addition to the ovary. In conclusion, the first goal of our research has been to produce a valid model of serous high-grade tumors. The second is to identify discrete characteristics of early serous carcinogenesis in the tube that can be exploited for early detection and to examine the causes of the earliest events preceding malignancy, which will create a great opportunity for cancer prevention in high-risk women. It is clear that events leading to the development of STICs play a significant role in the development of serous tumors. Resolving their pathogenesis will enable more efficient methods for early detection, tumor imaging, cancer prevention, and identification of populations at risk.

EXPERIMENTAL PROCEDURES

Development of Genetically Engineered Mouse Models

All animal studies and procedures were approved by the Dana Farber Cancer Institute and Harvard Medical School Animal Care and Use Committees. *PAX8-rtTA*, *TetO-Cre*, and *Gt (ROSA) 26Sor* strains (C57Bl background) were acquired from the Jackson Laboratory (Perf et al., 2002; Soriano, 1999; Traykova-Brauch et al., 2008). *Brca1^{fllox/fllox}* and *Brca2^{fllox/fllox}* mice were generated by insertion of *LoxP* sites into introns surrounding exon 11 in the *Brca1* and *Brca2* loci respectively, on a stock background (Jonkers et al., 2001; Xu et al., 1999). For the *Tp53^{fllox/fllox}* mice *LoxP* sites were inserted in introns 1 and 10 of the endogenous *Tp53* locus. *Tp53-LSL-R270H (Tp53^{R270H})* mice contain a dominant negative point mutant allele of *Tp53* that can be activated by *Cre*-mediated recombination (Olive et al., 2004). *Tp53^{fllox/fllox}* and the *Tp53^{R270H}* mice were a gift from Dr. Tyler Jacks (MIT). *Pten^{fllox/fllox}* mice were generated by inserting *LoxP* sites into the *Pten* locus flanking exon 5 (Lesche et al., 2002). Genotyping procedures are described in the Supplemental Experimental Procedures. In order to drive *Cre*-mediated recombination in murine FTSECs, we treated experimental and control mice for 14 days with Dox (Sigma) using a concentration of 0.2 mg/ml in their drinking water. Animals were routinely monitored for signs of distress, poor body condition, and tumor burden and were euthanized according to veterinary recommendations. For survival curve experiments, the mice were monitored until their death or upon veterinary recommendations.

Quantification of Serum CA-125 Levels

CA-125 levels in murine sera, which were collected via cardiac puncture during necropsy, were quantified using a USCN ELISA kit (Life Science) according to manufacturer's instructions. One hundred microliters of serum was used per sample for ELISA testing.

Array Comparative Genomic Hybridization

Mouse genomic DNA was isolated using Genra Puregene Cell Kit (QIAGEN) according to the manufacturer's instructions. Array comparative genomic hybridization (aCGH) was performed using whole genome Agilent SurePrint

G3 mouse CGH 1M catalog array (Agilent Technologies). Genomic DNA from three normal mouse FTs was pooled and used as a reference. One microgram of total genomic DNA from the reference and test samples (derived from murine HGSC tumors) was used to perform array CGH according to the manufacturer's protocol. Briefly, reference and test DNA were first fragmented using a heat block at 95°C for 5 min and then labeled with Cyanine 3/Cyanine 5 fluorescence-labeled nucleotides respectively, according to the BioPrime Array CGH Genomic Labeling protocol (Invitrogen). Labeled DNA was purified using Amicon Ultra-0.5 30 k purification columns (Millipore). Test and reference DNA were then combined and hybridized to the Agilent 1 M mouse catalog array for 40 hr at 65°C. The array slides were further washed and scanned. Probe signal intensities were obtained using the feature extraction software analysis provided by Agilent. Copy number alterations were identified using Nexus software analysis (BioDiscovery). The FASST2 segmentation algorithm was applied by setting the following parameters: a minimum number of five probes per segment were used to detect a copy number aberration with a significance threshold of 5×10^{-6} ; we further used log ratio cut offs of ± 0.3 to detect one copy gain/loss and ± 0.7 to detect high gain/homozygous loss.

Comparison with the Human TCGA Data Set

Mouse and human orthology information was obtained from the Mouse Genome Informatics database (<http://www.informatics.jax.org/mgihome/other/citation.shtml>) (Eppig et al., 2012) using the mm9 mouse genome reference assembly. The resulting regions were then compared to the alterations identified in the TCGA data set (Cancer Genome Atlas Research Network, 2011). The syntax “<gene name>:CNA >=GAIN” and “<gene name>:CNA ≤ HETLOSS” were used to query single copy gains and losses from the TCGA cBio portal, respectively (Cerami et al., 2012).

ACCESSION NUMBERS

The Gene Expression Omnibus accession number for the array comparative genomic hybridization (CGH) data files reported in this paper is GSE49827.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, six figures, and six tables and can be found with this article online at <http://dx.doi.org/10.1016/j.ccr.2013.10.013>.

AUTHOR CONTRIBUTIONS

R.P., D.M.D., and R.D. provided the concept design for these studies. R.P., G.A.W., K.W.M., D.M.D., and R.D. devised and designed the experiments. R.P. generated and characterized the *Pax8-Cre* deleter mouse. G.A.W., K.W.M., B.B.P., K.T.C., A.W.O., and C.D.S. developed and characterized the *Brca* FT animal models. R.P., G.A.W., and S.K. performed western blot analysis. J.G.B. performed immunohistochemical analysis. J.G.B., M.S.H., and C.P.C. provided expert pathological analysis, clinical insight, and pertinent suggestions. A.M.K. and R.D. generated FTSEC lines. J.H.C. and S.R.S. performed genomic experiments and bioinformatics analysis. R.P., G.A.W., K.W.M., A.W.O., S.R.S., D.M.D., and R.D. analyzed the data and wrote the manuscript.

ACKNOWLEDGMENTS

The authors wish to thank Christine Lam, Mei Zheng, and Huiying Piao for excellent technical assistance and the members of the Dinulescu and Drapkin labs for helpful discussions. We thank Dr. Andrew Godwin (University of Kansas Medical Center) for the HIO cells. This work is supported by grants from the National Institutes of Health, SPOR P50 CA105009 (to R.D.), EDNR U01 CA152990 (to R.D.), R21 CA156021 (to R.D.), DOD OCRP W81XWH-10-1-0263 award (to D.M.D.), American Cancer Society RSG-13-083-01-TBG award (to D.M.D.), Ovarian Cycle and Ovarian Cancer Research Fund Liz Tilberis award (to D.M.D.), Burroughs-Wellcome Fund Career Award in the Biomedical Sciences 1005320.01 (to D.M.D.), V Foundation for Cancer
