Management of Cirrhosis and Ascites

Pere Ginès, M.D., Andrés Cárdenas, M.D., Vicente Arroyo, M.D., and Juan Rodés, M.D.

CIRRHOsis, MOST FREQUENTLY CAUSED BY HEPATITIS C OR ALCOHOLISM, was the 12th leading cause of death in the United States in 2000, accounting for more than 25,000 deaths. Ascites is the most common complication of cirrhosis and is associated with a poor quality of life, increased risks of infections and renal failure, and a poor long-term outcome. In recent years, important advances have been made in the management of cirrhosis and ascites.

The chief factor contributing to ascites is splanchnic vasodilatation. Increased hepatic resistance to portal flow due to cirrhosis causes the gradual development of portal hypertension, collateral-vein formation, and shunting of blood to the systemic circulation. As portal hypertension develops, local production of vasodilators, mainly nitric oxide, increases, leading to splanchnic arterial vasodilatation. In the early stages of cirrhosis, splanchnic arterial vasodilatation is moderate and has only a small effect on the effective arterial blood volume, which is maintained within normal limits through increases in plasma volume and cardiac output. In the advanced stages of cirrhosis, splanchnic arterial vasodilatation is so pronounced that the effective arterial blood volume decreases markedly, and arterial pressure falls. As a consequence, arterial pressure is maintained by homeostatic activation of vasoconstrictor and antinatriuretic factors, resulting in sodium and fluid retention. The combination of portal hypertension and splanchnic arterial vasodilatation alters intestinal capillary pressure and permeability, facilitating the accumulation of retained fluid within the abdominal cavity. As the disease progresses, there is marked impairment in renal excretion of free water and renal vasoconstriction—changes that lead to dilutional hyponatremia and the hepatorenal syndrome, respectively.

PATHOPHYSIOLOGY OF ASCITES

The evaluation of patients with cirrhosis and ascites should include not only an assessment of liver function but also an assessment of renal and circulatory function (Table 1). Ideally, patients should be evaluated when they are not receiving diuretic agents, since some variables related to renal function may be altered by the administration of these medications. Ascitic fluid should be examined to rule out spontaneous bacterial peritonitis in patients with new-onset ascites, whether or not they are hospitalized, and especially in those who have signs of infection, abdominal pain, encephalopathy, or gastrointestinal bleeding.
EVALUATION FOR LIVER TRANSPLANTATION

All patients with ascites should be evaluated for transplantation, since the presence of ascites is associated with poor long-term survival (survival rate at five years, 30 to 40 percent, vs. 70 to 80 percent among patients who have undergone transplantation). The prognosis is not uniform among patients with ascites, but there is no widely accepted model for determining the prognosis for these patients. In clinical practice, the best method of identifying patients who may have a poor outcome is to recognize conditions associated with severe impairment of renal or circulatory function, such as refractory ascites, spontaneous bacterial peritonitis, or the hepatorenal syndrome (Fig. 2). Transplantation in patients with any of these three conditions should be given priority. In the United States, priority is assigned on the basis of the Model for End-Stage Liver Disease score, a quantitative index obtained with the use of a for-

mula that incorporates the serum bilirubin and creatinine concentrations and the international normalized ratio. This system has not been validated specifically for patients with ascites.

MANAGEMENT OF ASCITES

GENERAL MEASURES
Reduction of sodium intake is beneficial in patients with ascites, particularly those with severe sodium retention that does not respond or responds only minimally to diuretics. A low-sodium diet (60 to 90 mEq per day, equivalent to approximately 1500 to 2000 mg of salt per day) may facilitate the elimination of ascites and delay the reaccumulation of fluid. More stringent restriction is not recommended because it is poorly tolerated. Fluid intake should be restricted (to approximately 1000 ml per day) only in patients with dilutional hyponatremia, a condition characterized by a serum sodium concentration of less than 130 mmol per liter in the presence of ascites, edema, or both. Dilutional hyponatremia results from impaired renal excretion of free water due to inappropriately high concentrations of antidiuretic hormone.

SPECIFIC MEASURES

Moderate-Volume Ascites
In some patients, the amount of fluid in the peritoneal cavity is sufficient to cause moderate discomfort. Renal sodium excretion is not severely impaired in most of these patients, but they have a positive sodium balance because sodium excretion is low relative to sodium intake. The rate of accumulation of ascitic fluid is usually low, so large-volume ascites typically does not develop unless the sodium intake is high or there is a delay before medical assistance is sought. Renal free-water excretion and the glomerular filtration rate are normal in most cases; therefore, the serum sodium and creatinine concentrations are within normal limits.

Patients with moderate-volume ascites can be treated as outpatients and do not require hospitalization unless they have other complications of cirrhosis. In most cases, a negative sodium balance and loss of ascitic fluid are quickly achieved with low doses of diuretics. The diuretic of choice is either spironolactone (50 to 200 mg per day) or amiloride (5 to 10 mg per day). Low doses of furosemide (20 to 40 mg per day) may be added during the first few days to increase natriuresis, especially when peripheral edema is present. Furosemide should be used with caution because of the risk of excessive diuresis, which may lead to renal failure of prerenal origin. The recommended weight loss to prevent renal failure of prerenal origin is 300 to 500 g per day in patients without peripheral edema and 800 to 1000 g per day in those with peripheral edema. The response to diuretics can be evaluated on the basis of changes in body weight and by physical examination. Routine measurement of urinary sodium during diuretic therapy is not necessary, except in patients in whom there is no weight loss. In that situation, measurement of urinary sodium provides an exact assessment of the response to diuretics and may help in the decision whether to increase the dose of diuretics.
Large-Volume Ascites

Large-volume ascites — that is, ascites in an amount large enough to cause marked abdominal discomfort, which interferes with regular daily activities — can be treated on an outpatient basis unless there are associated complications. Patients with large-volume ascites usually present with severe sodium retention (urinary sodium concentration, less than 10 mmol per liter), so that ascitic fluid accumulates rapidly, even when sodium intake is restricted. Most patients with large-volume ascites have normal renal free-water excretion and a normal serum sodium concentration. In some, however, free-water excretion is impaired and dilutional hyponatremia may develop, either spontaneously or when fluid intake is increased. The serum creatinine concentration is normal or only moderately higher than normal, indicating that the glomerular filtration rate is normal or only moderately reduced.

There are two therapeutic strategies for large-volume ascites: large-volume paracentesis and the administration of diuretics at increasing doses (maximal doses, 400 mg of spironolactone per day and 160 mg of furosemide per day) until loss of ascitic fluid is achieved. The results of randomized trials comparing these two approaches support paracentesis as the method of choice. Although there is no difference between the two strategies with respect to long-term mortality, large-volume paracentesis is faster, is more effective, and is associated with fewer adverse events than diuretic therapy. Regardless of the strategy used, diuretics should be given as maintenance therapy to prevent recurrence of ascites. Removal of large amounts of ascitic fluid by paracentesis without the use of plasma expanders is associated with a derangement in circulatory function, characterized by a reduction of effective arterial blood volume and activation of vasoconstrictor and antinatriuretic factors. Circulatory dysfunction after large-volume paracentesis is associated with a high rate of recurrence of ascites, development of the hepatorenal syndrome or dilutional hyponatremia in 20 percent of cases, and shortened survival. Plasma expanders are effective in preventing this complication. Albumin is superior to dextran 70 and polygeline in preventing circulatory dysfunction after paracentesis involving the removal of more than 5 liters of fluid, but randomized studies show no significant difference in survival between patients treated with albumin and those treated with other plasma expanders, probably because of the studies’ sample sizes. Although the use of albumin in this setting remains controversial because of its high cost and the lack of a documented survival benefit, albumin has a greater protective effect on the circulatory system than other expanders, a feature that supports its use in patients treated with large-volume paracentesis.

Severe local complications related to paracentesis, such as infection or intestinal perforation, are exceedingly rare if the procedure is performed with an appropriate technique and with an appropriate needle. The incidence of clinically significant bleeding at the puncture site or hemoperitoneum is also extremely low, but most clinical trials have excluded patients with an elevated prothrombin time (more than 21 seconds), an international normalized ratio that exceeds 1.6, or a platelet count below 50,000 per cubic millimeter. The risk of bleeding complications in patients with more severe coagulopathy is unknown and warrants investigation.

Refractory Ascites

Refractory ascites, which occurs in 5 to 10 percent of patients with ascites, is defined as a lack of response to high doses of diuretics (400 mg of spironolactone per day). When ascites does not respond to diuretics, the clinician must consider the possibility that the patient’s ascites is “refractory” to diuretics, and alternative causes of ascites must be sought. If the patient is a candidate for paracentesis, an attempt should be made to remove more than 20 liters of fluid in a single session, and plasma expanders should be used in conjunction with paracentesis to maintain effective arterial blood volume and to correct the hyponatremia caused by diuretic therapy. If the patient is not a candidate for paracentesis, the physician may consider a trial of plasma expanders to determine whether the patient’s ascites is due to circulatory dysfunction. If the patient is not a candidate for paracentesis or plasma expanders, the physician may consider a trial of plasma expanders to determine whether the patient’s ascites is due to circulatory dysfunction.
Patients in whom there are recurrent side effects (e.g., hepatic encephalopathy, hyponatremia, hypokalemia, or azotemia) when lower doses are given are also considered to have refractory ascites. The main clinical features include frequent recurrence of ascites after paracentesis, an increased risk of type 1 hepatorenal syndrome (which is characterized by progressive oliguria and a rapid increase in the serum creatinine concentration), and a poor prognosis (Fig. 2). Current therapeutic strategies include repeated large-volume paracentesis with the use of plasma expanders and transjugular intrahepatic portosystemic shunts. The use of peritoneovenous shunts was abandoned because of significant rates of complications.

Repeated large-volume paracentesis plus albumin administration is the most widely accepted therapy for refractory ascites. Patients generally require paracentesis every two to four weeks, and the procedure can be performed in an outpatient setting. The main drawback is early recurrence of ascites, because paracentesis does not affect the mechanisms responsible for the accumulation of ascitic fluid.

In contrast to paracentesis, the use of a transjugular intrahepatic portosystemic shunt, which consists of an intrahepatic stent inserted between one hepatic vein and the portal vein by a transjugular approach, is effective in preventing recurrence in patients with refractory ascites. Transjugular intrahepatic portosystemic shunting decreases the activity of sodium-retaining mechanisms and improves the renal response to diuretics. The main disadvantages of this technique include a high rate of shunt stenosis (up to 75 percent after 6 to 12 months), which can lead to recurrence of ascites; hepatic encephalopathy; a high cost; and lack of availability in some centers.

Although it has been claimed that transjugular intrahepatic portosystemic shunting, as compared with large-volume paracentesis, improves survival in patients with refractory ascites, this finding was not confirmed in two recent, randomized studies. Therefore, the use of a transjugular intrahepatic portosystemic shunt should not be recommended as the treatment of choice for refractory ascites. This method should probably be reserved for patients without severe liver failure or encephalopathy who have loculated fluid that cannot be treated with paracentesis and for those who are unwilling to undergo repeated paracentesis. There is no evidence that transjugular intrahepatic portosystemic shunting improves either the likelihood of survival until liver transplantation or the outcome

The Hepatorenal Syndrome

The hepatorenal syndrome is characterized by renal failure due to severe vasoconstriction of the renal circulation. Pathogenetically, the hepatorenal syndrome consists of renal failure of hemodynamic origin resulting from extreme underfilling of the arterial circulation. It occurs in up to 10 percent of patients with advanced cirrhosis and ascites and may follow either of two clinical patterns (Table 3). In some patients, there is progressive oliguria and a rapid rise of the serum creatinine concentration. This condition is known as type 1 hepatorenal syndrome. A common precipitating event that triggers the impairment in renal function is spontaneous bacterial peritonitis. In other patients, most of whom have refractory ascites, the increase in the serum creatinine concentration is moderate and has no tendency to progress over time. This pattern is known as type 2 hepatorenal syndrome. The hepatorenal syndrome may be diagnosed after nonfunctional causes of renal failure are ruled out (Table 3). The prognosis is poor, particularly among patients with type 1 hepatorenal syndrome, who have a median survival of less than one month without therapy (Fig. 2).

Dopamine and prostaglandins are ineffective in treating patients with the hepatorenal syndrome. By contrast, vasoconstrictor drugs (vasopressin analogues or α-adrenergic agents), in combination with albumin, are effective in approximately two thirds of patients (Table 4). Octreotide is ineffective when administered alone, yet it has been reported to be beneficial when given in combination with midodrine. Whether octreotide improves the efficacy of midodrine is unknown. Recurrence of the hepatorenal syndrome is uncommon after the discontinuation of vasoconstrictors, although it is not currently known whether the recurrence rate differs between patients with type 1 hepatorenal syndrome and those with type 2. Patients who have a response to terlipressin have a higher rate of survival than patients who do not have a response. Therefore, treatment with vasoconstrictors may increase the likelihood that patients with the hepatorenal syndrome will survive long enough to undergo liver transplantation. In addition, these agents offer the advantage of improving renal function before transplantation — a benefit that may reduce post-transplantation morbidity and mortality.

Although emerging data on the use of vasoconstrictors for the treatment of hepatorenal syndrome are promising, additional research is needed to determine the optimal therapeutic approaches for these patients.
strictors in patients with the hepatorenal syndrome are very promising, the available information is still limited and is based only on nonrandomized studies involving small numbers of patients. Transjugular intrahepatic portosystemic shunting also appears to be effective in treating the hepatorenal syndrome, but again, the available information is insufficient. More research is needed to establish the role of these therapies in the management of this syndrome.

Hemodialysis should not be used routinely in patients with the hepatorenal syndrome because it does not improve the outcome. However, it may have a role as a bridge to liver transplantation in patients who do not have a response to medical therapy.

Spontaneous Bacterial Peritonitis
Spontaneous bacterial peritonitis is characterized by the spontaneous infection of ascitic fluid in the absence of an intraabdominal source of infection. Its prevalence among patients with ascites ranges between 10 and 30 percent. The presence of at least 250 polymorphonuclear cells per cubic millimeter of ascitic fluid is diagnostic of this condition. Aerobic gram-negative bacteria, primarily *Escherichia coli*, are the most common isolates, although the frequency of episodes caused by gram-positive bacteria has recently increased. Spontaneous bacterial peritonitis involves the translocation of bacteria from the intestinal lumen to the lymph nodes, with subsequent bacteremia and infection of ascitic fluid. Third-generation cephalosporins are the treatment of choice. The most severe complication of spontaneous bacterial peritonitis is the hepatorenal syndrome, which occurs in up to 30 percent of patients and carries a high mortality rate. Intravenous albumin (1.5 g per kilogram of body weight at diagnosis and 1 g per kilogram 48 hours later) helps to prevent the hepatorenal syndrome and improves the probability of survival. This regimen is empirical, and no information exists on the efficacy of lower albumin doses or other plasma expanders. After resolution, spontaneous bacterial peritonitis frequently recurs, with an estimated 70 percent probability of recurrence at one year. Long-term antibiotic prophylaxis with quinolones (norfloxacin, 400 mg per day orally) reduces the rate of recurrence, but spontaneous bacterial peritonitis caused by quinolone-resistant bacteria is an emerging problem. Trimethoprim–sulfamethoxazole may be an alternative to quinolones, but the information available with respect to its efficacy is very scarce. Long-term antibiotic prophylaxis has a beneficial effect on patients' survival, probably because of the high mortality rate associated with spontaneous bacterial peritonitis. Nonetheless, this idea has not been specifically assessed in a clinical trial.
